1 Exercises precipitation

1.1 Exercise 1 - Interpolate missing values

The figure shows the location of 11 precipitation gages in a research watershed. Measurements are missing at gage F for a rain storm. Use the records from the other gages (shown in the following table) to fill the gap in the rainfall amount in gage F.

The file RainfallData Exercise 001.csv contains the rainfall data.

Gage	X	Y	Average Annual Precip. (mm)	Measured Storm Precip. (mm)
$\overline{\mathrm{C}}$	385014	4778553	1404	11.6
D	389634	4779045	1433	14.8
\mathbf{E}	380729	4775518	1665	13.3
\mathbf{F}	387259	4776670	1137	-
G	389380	4776484	1235	12.3
H	382945	4772356	1114	11.5
I	386399	4771795	1101	11.6
J	388397	4772419	1086	11.2
K	389287	4771097	1010	9.7

Methods: Section 1.1.2 Section ?? Section 1.1.4

Missing data completion methods and interpolation methods are both based in the following general equation:

$$\hat{p_o} = \sum_{i=1}^n w_i \cdot p_i$$

Where $\hat{p_o}$ is the rainfall value to be filled/interpolated, n is the number of gages used to interpolate, w_i and p_i are the weighting factor and the rainfall value in each of those gages.

```
[1]: import numpy as np
import pandas as pd

from matplotlib import pyplot as plt
%matplotlib inline
# plt.style.use('dark_background')
plt.style.use('seaborn-whitegrid')
```

1.1.1 Import data

K

Import data using pandas and save it in an object (data frame using pandas terminology).

```
[2]: # Import 'RainfallData_Exercise_001.csv'
data1 = pd.read_csv('..\data\RainfallData_Exercise_001.csv', index_col=0)
data1
```

```

9.7

Data frames have a series of attributes associated. For instance, we can ask for the dimensions of the table (shape), the number of elements (size), the name of the rows or columns (index or

columns) or extract the data as a numpy array (values).

To call an attribute, type: DataFrame.attribute

- [3]: # dimension data1.shape
- [3]: (11, 4)
- [4]: # n. of elements
 data1.size
- [4]: 44
- [5]: # row names
 data1.index
- [5]: Index(['A', 'B', 'C', 'D', 'E', 'F', 'G', 'H', 'I', 'J', 'K'], dtype='object', name='Gage')
- [6]: # column names
 data1.columns

Apart from attributes, we can apply any kind of function to a *data frame*. For instance, describe shows a statistical summary of the variables in the *data fram*.

To apply a function, type: DataFrame.function()

[7]: # summary data1.describe()

```
[7]:

To extract a datum or a subset of data from a *data frame*, we must indicate row and column by either the name or the position. * Function .loc extracts subsets of a *data frame* calling the row and column names. * Function .iloc does the same, but using the row and column position. WARNING: Python positioning starts from 0, so the first row is row number 0 instead of 1.

```

```

1.1.2 The station-average method

In this method, we assume that rainfall in the target point is the average rainfall in the surrounding gages.

Following the general equation, we give the same weight w_i to every gage.

$$w_i = \frac{1}{n}$$

$$\hat{p_o} = \frac{1}{n} \sum_{i=1}^{n} p_i$$

where n is the number of gages.

```
[14]: po_mm = data1['p'].mean()
```

```
[15]: print('Rainfall in F is:')
print('pf =', round(po_mm, 1), 'mm')
```

```
Rainfall in F is:
pf = 12.3 mm
```

When averaging rainfall throughout all the available gages, we obtain a smoothed value of rainfall in F. That is, we may be using data from stations so far away from the study point that there is no connection between rainfall values in those two stations.

To avoid this problem, the station-average method is usually applied using only the closest gage to the study point in each quadrant.

```
[16]: closest = ['C', 'D', 'G', 'I']
   po_mmc = data1.loc[closest, 'p'].mean()

   print('Rainfall in F is:')
   print('pf =', round(po_mmc, 1), 'mm')
```

```
Rainfall in F is:
pf = 12.6 mm
```

1.1.3 The normal-ratio method

The normal-ratio is the quotient between the annual precipitation in two gages.

$$NR_i = \frac{P_o}{P_i}$$

We can use this value as a measure of the connection of the rainfall amounts between those gages. The normal-ratio method applies the normal-ratio as a correction to the weights derived by the station-average method.

$$w_i = \frac{1}{n} \frac{P_o}{P_i} = \frac{1}{n} N R_i$$

$$\hat{p_o} = \frac{1}{n} \sum_{i=1}^n \frac{P_o}{P_i} p_i$$

Where P_o and P_i are annual precipitation in the point of interest and the available gages, respectively, and NR is the normal-ratio.

```
[17]: # Extract stations with data during the storm
data1_ = data1.drop('F').copy()
data1_
```

```

[20]: # the mean of that product is the rainfall interpolated by the normal-ratio_
       \rightarrowmethod
      po_rn = data1_['NR*p'].mean()
      print('Rainfall in F is:')
      print('pf =', round(po_rn, 1), 'mm')
     Rainfall in F is:
     pf = 10.9 mm
[21]: # All at once
      po_rn = np.mean(data1_.loc[:, 'RN'] * data1_.loc[:, 'p'])
      print('Rainfall in F is:')
      print('pf =', round(po_rn, 1), 'mm')
     Rainfall in F is:
     pf = 10.9 mm
     We can also apply the normal-ratio method to the closest gage in each quadrant
[22]: po_rnc = np.mean(data1_.loc[closest, 'RN'] * data1_.loc[closest, 'p'])
      print('Rainfall in F is:')
      print('pf =', round(po_rnc, 1), 'mm')
     Rainfall in F is:
     pf = 11.1 mm
```

1.1.4 The inverse distance method

The inverse distance method is based on the assumption that gages closer to the point of interest are more representative of its rainfall. In this methods, gage weights are estimated as the inverse of the distance to a power. Since the sum of weights must be 1, we normalize the weighted inverse distances dividing them by their sum.

$$w_i = \frac{d_i^{-b}}{\sum_{i=1}^n d_i^{-b}}$$

$$\hat{p_o} = \sum_{i=1}^n \frac{d_i^{-b}}{\sum_{i=1}^n d_i^{-b}} \cdot p_i = \frac{1}{\sum_{i=1}^n d_i^{-b}} \sum_{i=1}^n d_i^{-b} \cdot p_i$$

Where d_i is the distance between gage i and target point, and b is the power to be chosen by the modeller.

A squared power (b = -2) is usually applied, what is named the squared inverse distance method. The larger the exponent, the higher weight is given to the closer gages.

```

[32]: # compute rainfall in F
      po_di2 = np.sum(data1_['di2'] / np.sum(data1_['di2']) * data1_['p'])
      print('Rainfall in F:')
      print('pf =', round(po_di2, 1), 'mm')
     Rainfall in F:
     pf = 12.4 mm
     Again, we can apply the inverse distance method only to the closest station per quadrant.
[33]: # compute rainfall in F
      po_di2c = np.sum(data1_.loc[closest, 'di2'] * data1_.loc[closest, 'p']) / \
                np.sum(data1_.loc[closest, 'di2'])
      print('La precipitación en F es:')
      print('pf =', round(po_di2c, 1), 'mm')
```

```
La precipitación en F es:
pf = 12.5 mm
```

Comparativa de métodos

```
[34]: # create an array with all the results
results = np.array([po_mm, po_mmc, po_rn, po_rnc, po_di1, po_di2, po_di2c])
```

```
[36]: po_mm po_mmc po_rn po_rnc po_di1 po_di2 po_di2c 0 12.26 12.575 10.938378 11.110048 12.333644 12.382834 12.539028
```

```
[37]: # export results as a csv
results.to_csv('../output/Ex1_compare methods.csv', index=False,

→float_format='%.1f')
```

1.1.5 Interpolation

The methods aboved explained may also be used in spatial interpolation, i.e., to generate maps of precipitation.

We are going to create a precipitation map using the inverse distance weighted method. To do that, we are going to create a *Python* functions that performs IDW.

```
[38]: def IDW(x, y, stnX, stnY, stnP, b=-2):
           """Interpolate by the inverse distance weighted method
          Parameters:
          x:
                    float. Coordenate X of the target point
                    float. Coordenate Y of the target point
          stnX: Series. Coordenates X of the gages stnY: Series. Coordenates Y of the gages
          stnP: Series. Observed precipitation in the gages
                   int. Exponent in the inverse distance
          b:
          Returns:
                    float. Precipitation interpolated for point (x, y)
           11 11 11
          # distance to the target point
          distX = x - stnX
                                                # distancia en el eje X
          distY = y - stnY
                                                # distancia en el eje X
          dist = np.sqrt(distX**2 + distY**2) # distancia total
          # inverse of the distance
          idw = dist**b
          # interpolate
          p = np.sum(idw / np.sum(idw) * stnP)
          return round(p, 1)
```

```
[39]: # check the function in point F

IDW(data1.loc['F', 'X'], data1.loc['F', 'Y'], data1_['X'], data1_['Y'],

data1_['p'], b=-2)
```

[39]: 12.4

Now we can apply the function to a grid of cells representing an area.

```
[40]: # Coordenates X and Y of the grid
     xo, xf = 382200, 390200
     X = np.arange(xo, xf, 100)
     yo, yf = 4771400, 4779400
     Y = np.arange(yo, yf, 100)
[41]: # create empty map (zeros) with the dimensions of 'X' and 'Y'
     pcp = np.zeros((len(X), len(Y)))
 []: # interpolate rainfall in each cell of the gridr la precipitación en cada una
      →de las celdas del mapa
     for i, y in enumerate(Y[::-1]): # important to invert the position of 'Y'
         for j, x in enumerate(X):
             pcp[i, j] = IDW(x, y, data1_.X, data1_.Y, data1_.p, b=-2)
 []: # gráfico con las estaciones y el mapa de precipitación interpolada
      # -----
     # configuración
     plt.figure(figsize=(6, 6))
     plt.axis('equal')
     # mapa interpolado
     pmap = plt.imshow(pcp, extent=[xo, xf, yo, yf], cmap='Blues')
     cb = plt.colorbar(pmap)
     cb.set_label('precipitación (mm)', rotation=90, fontsize=12)
     # puntos con las estaciones
     plt.scatter(data1_.X, data1_.Y, c='k', s=data1_.p**3/30);
     plt.savefig('../output/Ex1_precipitation map.png', dpi=300)
 []:
```
